EXECUTIVE SUMMARY

High rates of spill are presumed to increase passage survival for juvenile salmonid migrants because passage survival through spillways at Columbia and Snake River dams is generally higher than through turbines. However, two conditions at The Dalles Dam may decrease spill passage survival under high spill conditions: 1) a short stilling basin and shallow tailrace result in severe turbulence and lateral currents that may cause physical injury to migrant salmon; and 2) a large proportion of spillway-passed water moves through shallows and islands downstream, where predation on salmonids by gulls (*Larus spp.*) and northern pikeminnow (*Ptychocheilus oregonensis*) may be substantially higher.

In 1997, the National Marine Fisheries Service initiated a study at The Dalles Dam to evaluate survival of juvenile Pacific salmon (*Oncorhynchus* spp.) passed through the spillway when 64% of the river flow was spilled. Results of the 1997 tests suggested losses of about 13% for coho salmon (*O. kisutch*) and 8% for subyearling chinook salmon (*O. tshawytscha*) passing at 64% spill.

In 1998, we expanded the research objectives to include assessment of passage survival through the spillway at high flow (64% of river flow) and moderate flow (30% of river flow) and through the ice and trash sluiceway during daytime periods at moderate flow. Results of the 1998 tests suggested losses of about 11% for coho salmon during the spring migration at 64% spill and 25% for subyearling chinook salmon during the summer migration at 64% spill. At the 30% spill level, losses were much lower at about 3% for coho salmon during the spring migration and 11% for chinook salmon during the summer migration. At 30% spill, losses through the sluiceway were similar to those through the spillway at 4% for coho salmon and 11% for chinook salmon.

In 1999, we continued passage survival tests comparing 30 to 64% spill conditions, but excluded the sluiceway component of the study in order to increase test fish numbers, and thus precision, for the spillway passage evaluations. Test fish were collected from the fish collection facility at John Day Dam and tagged with passive integrated transponder (PIT) tags. Approximately 139,000 yearling chinook and coho salmon were tagged in April and May (spring migrants) and 167,000 subyearling chinook salmon were tagged in June and July (summer migrants).

About 50% of the test fish were released through the spillway at either 30 or 64% spill (~25% each), and about 50% were released in the tailrace as survival reference groups. Half of the test fish were released at night and the other half in daylight. The tailrace groups were released at a site away from turbulence and areas of suspected predation, and at a time to coincide with passage of treatment groups. The spillway releases were apportioned, as equally as possible, to three lateral locations in the spillway forebay, and spill conditions were alternated every 3 days between 30 and 64% of the river flow.

After migrating through 73 km of reservoir, a similar distance to previous years, a portion of the test fish passed through the Bonneville Dam PIT-tag interrogation equipment located in the juvenile fish bypass systems at Columbia River Kilometer (RKm) 235. About 16.2% of yearling chinook and coho salmon (spring migrants) and 12.2% of subyearling chinook salmon (summer migrants) released at The Dalles Dam were interrogated in the bypass systems at Bonneville Dam in 1999. Additionally, 4.3% of the spring migrants and 1.5% of the summer migrants were interrogated in the estuary off Jones Beach at RKm 75 or on abandoned piscivorous bird colonies at RKm 35 and RKm 8.

Point estimates of relative passage survival at 64% spill were 93% for spring migrants (CI 90-97%) and 96% for summer migrants (CI 92-100%). Point estimates at 30% spill were slightly higher than at 64% spill, with relative survival estimates of 96% for spring migrants (CI 92-101%) and 100% for summer migrants (CI 95-104%). Nighttime passage data produced significantly higher relative survival rates than daytime passage data for both the spring and summer migration. By design, these point estimates of survival represent passage survival of mixed fish stocks throughout the migration period; during daytime and nighttime; through spillbays across the width of the spillway; and at ambient spill gate openings, river flows, tailwater elevations, and water temperatures.

Mean travel time to Bonneville Dam averaged 1.8 days for both spring and summer migrants. Travel times were consistently less for tailrace-released (reference) groups than for spillway-released (treatment) groups, with a difference of 0.2 days for spring migrants and 0.1 days for summer migrants.

Tests of passage distribution homogeneity at Bonneville Dam for corresponding spillway- and tailrace-released groups of yearling spring and subyearling summer migrants suggested that daily release groups were not mixed on 28 of 60 test dates. To assess these distribution differences, we compared the number of fish detected from spillway and tailrace release groups in relation to powerhouse operation and river flow. We found negligible differences in powerhouse operations between mixed and non-mixed groups. Analyses of survival estimates between groups that were mixed upon arrival at Bonneville Dam and those that were not mixed produced no significant differences.

Relative survival estimates calculated from PIT-tag detections at Bonneville Dam were consistently lower than those calculated from detections at abandoned bird colonies in the estuary. There are diel behavioral changes for fish and avian predators which may bias PIT-tag detections at both Bonneville Dam and in the estuary. We utilized the combined data from all recovery sites for passage survival analyses.

During the study, spring flows ranged from 5,549 to 15,763 m³/second (196,000 to 557,000 ft³/second) and summer flows ranged from 4,726 to 14,235 m³/second (167,000 to 503,000 ft³/second).

Based on data collected through the third year of this study, we arrived at the following conclusions:

- 1) Detection rates of fish released through the spillway at 64% spill were significantly less than for fish released downstream from The Dalles Dam.
- 2) In the two years of direct comparison between spill rates, point estimates of relative survival for fish passing at 64% spill have been lower than for fish passing at 30% spill, but these differences have not been statistically significant. However, when annual data from 1998 and 1999 were combined for analysis, the differences were significant for spring migrants ($P = 0.05$) and for summer migrants ($P = 0.04$): respective point estimates for passage survival at 64 and 30% spill were 92 and 98% for spring migrants and 86 and 95% for summer migrants.
- 3) Data from three years of research has indicated that spillway passage during daytime hours (adult spill patterns) produces substantially lower passage survival than spillway passage during nighttime hours (juvenile spill patterns). Respective point estimates of survival during daytime vs. nighttime passage were 90 vs. 97% for spring migrants ($P = 0.04$) and 86 vs. 98% for summer migrants ($P < 0.01$).
- 4) Data from the 1998 evaluation of sluiceway passage indicated that for daytime passage at 30% spill, relative survival for daytime fish passage through the sluiceway was similar to that of daytime fish passage through the spillway (1 year of testing).
- 5) Evaluations of survival in relation to tailwater elevation, spill volume, river flow, and water temperature have indicated poor correlations in both spring and summer tests.

The following are recommendations for research in 2000:

- 1) Evaluate a single, constant spill rate of less than 64% with juvenile spill patterns during 24 hours/day and include sluiceway- and turbine-passage survival. Maximum fish numbers should be used to obtain the highest possible statistical sensitivity.
- 2) Continue evaluations that include detection data from PIT tags deposited in estuarine and lower-river bird colonies to provide increased detection numbers.
- 3) Continue assessment of differences between detection sites and evaluate combined data from 1997, 1998, 1999, and future years.
- 4) Minimize operations of the sluice chute at Bonneville Dam Second Powerhouse to maximize the PIT-tags detected at Bonneville Dam.

INTRODUCTION

Based on the 1995 National Marine Fisheries Service Biological Opinion (NMFS 1995), the U.S. Army Corps of Engineers (COE) selected the spillway as the best passage route for migrating juvenile salmon (*Oncorhynchus* spp.) at The Dalles Dam. NMFS recommended increasing spill volumes to 64% of river flow to attain 80% fish passage efficiency (FPE). High volumes of spill at The Dalles Dam produce levels of total dissolved gas (TDG) that are lower than those produced at other dams: during 1996, high volumes of spill at The Dalles Dam produced levels of TDG which were less than 120% of saturation, the maximum approved by state water quality agencies. Because TDG is not a factor that limits spill operations at The Dalles Dam, implementation of alternatives for increasing FPE, such as surface collectors or turbine intake screens with an upgraded sluiceway or bypass system, were deferred in lieu of increased spill.

However, observations at The Dalles Dam, and from the hydraulic model of the dam at the COE Waterways Experiment Station, have raised concerns about passage survival of juvenile salmonids during high spill. Heavy turbulence, back eddies, and lateral flow in the spillway stilling basin may be severe enough to injure fish, and water flows passing through the Bridge Islands downstream from the dam might cause higher-than-expected mortality due to predation (Fig. 1).

Substantial predation by northern pikeminnow (*Ptychocheilus oregonensis*) and gulls (*Larus* spp.) is suspected in the reef and islands area, based upon northern pikeminnow abundance and stomach-content evaluations (Hansel et al. 1993, Ward et al. 1995) and upon observations of salmonid smolts carried off by gulls (Jones et al. 1997; John Snelling, Oregon Cooperative Fisheries Research Unit, Oregon State University, Corvallis, OR 97331-1961, Pers. commun., November 1997). Survival tests conducted in 1995 (Normandeau Associates et al. 1996) corroborated concerns that heavy turbulence in the spillway stilling basin might cause unacceptable increases in mortality.

In 1996, we began discussions with the COE on means to test the premise that high spill levels at The Dalles Dam increase passage survival of migrating juvenile salmonids. A comprehensive review of potential methodologies indicated that assessments of spill passage survival at The Dalles Dam could be conducted using balloon tags, coded-wire tags, or passive integrated transponder (PIT) tags. Balloon tags are appropriate for evaluations of immediate and direct injury and mortality from shear currents and high-velocity impact with structures during dam passage, but not for evaluation of indirect mortality from predation during passage through the tailrace and downstream reservoir. Coded-wire-tag technology provides the ability to effectively evaluate both direct and indirect mortality; however, results are dependent on adult returns, and thus the number of fish necessary for the study would be unacceptably large. Therefore, we selected PIT tags because they provided the only method to evaluate both direct and indirect mortality using feasible numbers of test fish.

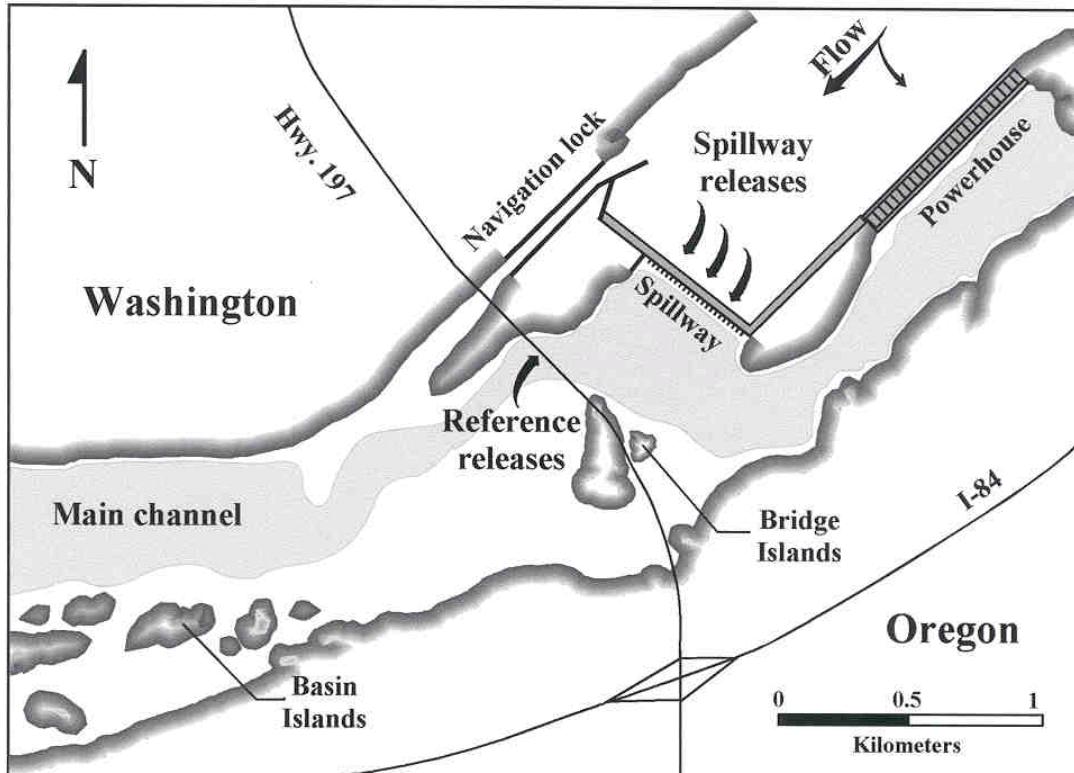

Figure 1. Overview of The Dalles Dam and tailrace area. Spillway and reference group release locations used in the 1999 evaluation of relative survival of juvenile coho salmon, yearling chinook salmon, and subyearling chinook salmon are shown, as well as the position of the main channel in relation to the shallow island areas downstream from the dam.

In 1997, our study objective was to estimate the relative survival of juvenile coho salmon (*O. kisutch*) and subyearling fall chinook salmon (*O. tshawytscha*) passing through The Dalles Dam spillway under 64% spill conditions. Data collected in 1997 from releases of approximately 43,000 coho salmon and 53,000 subyearling chinook salmon suggested survival of about 87 and 92%, respectively (Dawley et al. 1998).

In 1998, we expanded the research to include assessment of passage survival through the spillway at high spill (64% of river flow) and moderate spill (30% of river flow) and through the ice and trash sluiceway during the daytime at moderate spill. In 1998, passage survival for coho salmon was estimated at 89% through the spillway during high flow, 97% through the spillway during moderate flow, and 96% through the sluiceway during moderate flow. Passage survival for subyearling chinook salmon was estimated at 75% through the spillway during high flow, 89% through the spillway at moderate flow, and 89% through the sluiceway at moderate flow (Dawley et al. 2000).

In 1999, we repeated the 1998 tests with increased precision, but excluded the sluiceway component of the study. Point estimates of dam passage survival were again calculated for juvenile salmon during the spring and summer migration periods. Relative survival estimates were based on PIT-tag detections at Bonneville Dam and other downstream sites. Detection percentages of treatment groups released upstream from the spillway were compared to those of reference groups released downstream from the dam, thus providing relative survival estimates.

METHODS

During the spring migration, we captured run-of-the-river juvenile yearling chinook and coho salmon 5 to 7 days/week at the fish-collection facility at John Day Dam [Columbia River Kilometer (RKm) 347] in late April and May. During the summer migration in late June and July, we captured run-of-the-river subyearling chinook salmon 5 to 7 days/week at the same fish-collection facility. We PIT tagged approximately 6,000 fish daily and divided them proportionally among spillway (treatment) and tailrace (reference) groups (Fig. 1).

Tagged fish groups were then transported to The Dalles Dam (RKm 308) and held for 1 day before release upstream from the spillway or in the midstream area of the tailrace. Analyses of relative survival rates were based on subsequent PIT-tag detections from the juvenile bypass systems at Bonneville Dam First and Second Powerhouses (RKm 235), from the PIT-tag detector trawl used in the estuary off Jones Beach (RKm 75), and from flat-plate and pole-mounted detectors used on abandoned bird colonies at RKm 35 and RKm 8 (Ryan et al. in press).

Generally, juvenile salmon for each day of marking were captured during a 6- to 10-hour period from the fish bypass system at John Day Dam. As migrants passed out of the corrugated flume, they slid across a dewatering screen onto the wetted separator, which segregates juvenile

salmon from larger fish and debris. Upon separation, juvenile fish were directed through a 25-cm-diameter PIT-tag detector tunnel to a 3-way rotating gate, where previously PIT-tagged fish were returned to the river and non-tagged fish were diverted through a 25-cm pipe to the juvenile-fish sampling room. At the sampling room, fish were collected in a 6.1-m-long by 152-cm-wide by 107-cm-deep tank and held for marking.

Marking began each evening at 2000 h, when the smolt monitoring sample rate was increased to collect the target number of fish for tagging. The sample rate was initially increased to 25 or 33%, depending on the number of fish collected the previous night and the number of fish passing during that day. Adjustments to the sample rate were made hourly, as needed to collect the required number of fish for tagging, and ranged from 5 to 100%.

After fish were anesthetized, target fish were sorted, scanned for PIT tags, and tagged in approximately equal numbers for spillway (treatment) and tailrace (reference) groups. Taggers alternated between treatment and reference groups throughout the study period. Non-target fish and the occasional PIT-tagged target fish (fish not diverted back to the river at the 3-way rotating gate) were allowed to recover from anesthetic and were then released into the exit flume and returned to the river.

Tagged treatment and reference groups were routed to 800-L insulated aluminum holding tanks and held at maximum densities of less than 24 g/L for mixed coho and spring/summer chinook salmon (825 fish/tank, assuming 23 g average fish weight) and less than 13 g/L for subyearling chinook salmon (1,000 fish/tank, assuming 10.5 g average fish weight). Containers were maintained near ambient river temperature and oxygen concentration with about 75 L/minute water flow.

Generally, holding tanks were transported by truck to The Dalles Dam in the morning. During the 40-minute transport, oxygen was metered into tanks through air stones. When water temperatures approached 20°C, ice was added to each tank to prevent further increases during the transport period. At The Dalles Dam, water was distributed to each tank at a rate of about 45 L/minute. Fish were generally held until the following morning or the following night, then released. Before release, tanks were inspected for mortalities and loose PIT tags. Tanks were then loaded onto trucks supplied with oxygen and taken to the spillway or tailrace, where they were set on boats and ferried to the release site.

Test Conditions

Tests were designed to evaluate passage survival at spill levels of 64 and 30% of river flow alternating in 3-day periods; however, actual spill levels varied as much as 8% with averages of 30% (SD 2.2%) and 62% (SD 2.4%; Appendix Tables A1-A4). Passage conditions through each spillbay were different and changed through time in association with changes in river flow and hour of the day.

Spill gate openings varied for each spillbay based on the established spill patterns developed to maximize juvenile salmon survival without disrupting adult fish passage

(COE 1997). During nighttime, the juvenile spill pattern is utilized (from 2001 to 0500 h, when spill is greatest on the north side of the spillway). During daytime, the adult spill pattern is utilized (from 0500 to 2000 h, when spill is less at 3 or 4 north- and south-end spillbays and crowned in the center bays). The exception was Spillbay 9, which was closed from 21 April through the daytime release on 27 April. This spillbay was set with an opening of 1.5 m (5 ft) on 27 April for the nighttime release, and it remained at that setting through the remainder of the test period.

Releases were made through the duration of the yearling chinook salmon migration (spring migrants) and at the beginning and peak of the subyearling chinook salmon migration (summer migrants). The experimental design called for releases to be evenly divided between daytime and nighttime (adult and juvenile spill patterns).

Release Methods, Locations, and Times

Daily releases were made from 22 April to 29 May for yearling chinook and coho salmon (spring migration), and from 17 June to 19 July for subyearling chinook salmon (summer migration). Spillway groups were released first, followed by tailrace (reference) groups released about 15 minutes later. Daily releases generally alternated between daylight and dark periods throughout both tests. Spillway and tailrace groups on boats were both released from tanks held at an elevation of about 0.5 m above the water surface.

Daily spillway (treatment) releases were evenly distributed among the north, middle, and south portions of the forebay, with all groups released from a boat about 200 m upstream from the spill gates (Fig. 1). The order of releases was randomized. Tailrace (reference) releases were made from a boat downstream from the dam at the proposed site of the new bypass system outfall (Fig. 1). This site is about 70 m from the Washington shore, about 0.7 km downstream from the spillway, and about 30 m downstream from the Highway 197 bridge in an area of high water-velocity. At this location, released fish are thought to generally pass down the north side of the river, away from predator sanctuary areas (Snelling and Mattson 1998).

We attempted to make all test fish releases during peak periods of daily passage for naturally migrating fish (based on hydroacoustic data; BioSonics 1997). Release times varied, but the mean daytime release time was 1128 h for the spring migration and 1114 h for the summer migration, while the mean nighttime release time was 2052 h for the spring migration and 2254 h for the summer migration (Appendix Tables A1-A4). The average time from the first to last daily release was about 1 hour.

To accurately evaluate relative survival differences in exclusive relation to the effects of dam passage, it is important that treatment and reference groups migrate together (mixed) past the sampling and detection sites: homogeneity in passage ensures that physical conditions other than passage route are comparable. Differential timing or migration route through a river reach

could cause differences in predation and PIT-tag detection rates not directly attributable to dam passage.

To achieve mixing of test fish exiting the tailrace, treatment and reference groups were released sequentially in relation to water-particle travel time from release location to the tailrace exit. Unfortunately, the passage route taken by fish through the dam (i.e., powerhouse, proposed new bypass system, or spillway) affects the lateral location of fish in the tailrace, which in turn affects its passage route and movement rate downstream (Snelling and Mattson 1998). Therefore, some differences in timing from The Dalles Dam to Bonneville Dam were likely related to route of passage through The Dalles Dam. Different arrival timing at Bonneville Dam and in the estuary may affect the comparability of detection rates between groups because of temporal differences in river flow, Bonneville Dam operations, and fish and bird behavior in the estuary.

PIT-Tag Detection Methods and Locations

For this study, PIT-tag detection data was collected from three general areas. First, the majority of tags were detected at smolt bypass systems in the first and second powerhouses of Bonneville Dam (Dawley et al. 1998). Second, detections were made in the estuary off Jones Beach using a pair-trawl fitted with a PIT-tag detector in the cod end (Ledgerwood et al. in prep.). Third, land-based detections were made with flat-plate and pole-mounted PIT-tag detectors used at abandoned piscivorous bird colonies. These colonies were on East Sand and Rice Island (RKm 8 and 34, respectively), on channel markers in the estuary upstream from Rice Island, and upstream from The Dalles Dam on Little Memaloose and Little Miller Islands (RKm 314 and 331, respectively; Ryan et al. in press).

Tags detected on islands upstream from The Dalles Dam were not used to compute relative survival because they represented mortalities to the treatment groups. However, tags detected in the estuary were far downstream from the bird-foraging areas between The Dalles and Bonneville Dams, and thus represented test fish that survived passage through Bonneville Dam and migration through an additional 200 km of river.

Test Fish

Juvenile yearling chinook and coho salmon were used to evaluate spill passage survival at The Dalles Dam during the spring migration period. To limit handling impacts to fish listed under the Endangered Species Act, we did not separate hatchery and wild fish but used both as they arrived at the collection facility. Sorting out wild fish and tagging only hatchery fish would have necessitated the handling of, and consequent stress to, many more wild fish. Subyearling fall chinook salmon were used as test fish during the summer migration period.

Based on previous work, we estimated that detection rates at Bonneville Dam from PIT-tagged fish released in The Dalles Dam tailrace would average 15% for the spring migration and 10% for the summer migration (Dawley et al. 1999). To obtain the desired sensitivity of an 8 and 10% detectable difference between treatment and reference groups, the calculated numbers (Cochran and Cox 1957) of test fish needed were 140,000 spring fish and 168,000 summer fish.

Data Analyses

The primary null hypothesis tested was:

$H_{0(1)}$: Detection rates of treatment groups released to the spillway at 64% spill and to the spillway at 30% spill do not differ from those of reference groups released to the tailrace of The Dalles Dam.

Secondary null hypotheses, which were not necessarily expected to be rejected with one year's data (because of limited test fish numbers) were as follows:

$H_{0(2)}$: There are no differences in relative survival between treatment groups associated with release time (day or night) and lateral release location in the spillway (north to south segments).

$H_{0(3)}$: Relative survival for groups released through the spillway is not correlated with river volume, spill volume, tailwater elevation, or water temperature.

$H_{0(4)}$: Relative survival does not differ with size at realease between small and large fish, where the threshold between small and large is defined at 125 mm for yearling fish and 110 mm for subyearling fish.

$H_{0(5)}$: Detection proportions (treatment to reference release groups) did not differ with site of detection between Bonneville Dam First Powerhouse, Bonneville Dam Second Powerhouse, Jones Beach, and the estuarine bird rookeries.

$H_{0(6)}$: Arrival timing and passage distributions at Bonneville Dam do not differ between treatment and reference groups.

Detection percentages of daily release groups passing the spillway at 64 and 30% spill were compared to those of pooled reference groups (pooled by day) released in the tailrace: means and 95% confidence intervals were calculated from the natural log of treatment to reference detection proportions. Relative survival (detected proportion of spillway-released fish/detected proportion of tailrace-released fish) was calculated in relation to passage variables, which were categorized as follows: Julian date; spill percentage, indexed as 1 for 30% or 2 for 64% spill rates; release period, indexed as 1 for daytime (adult spill pattern) and 2 for nighttime (juvenile spill pattern); spillway release location, indexed as 1 for north bays, 2 for middle bays,

or 3 for south bays. Assessments were made using analysis of variance (ANOVA) of log-transformed detection ratios (treatment/reference).

Correlation coefficients were calculated for the relative survival estimates in relation to dependent variables (Julian date, tailwater elevation, river flow, spill flow, and water temperature) and stepwise linear regressions were conducted to evaluate the predictive potential of log-transformed survival ratios. Data from 1997, 1998, and 1999 used for this evaluation were pooled by release period.

Relative survival in relation to body size at release was evaluated to provide information regarding the effects of size selection on survival. Information from this analysis will be useful in future research activities, when a full range of fish sizes may not be available. Fish were divided into two groups: fish smaller than the size necessary for radio-transmitter implantation and fish larger than this size. The size thresholds presently utilized as minimum for radio tagging are 125 mm for yearling fish and 110 mm for subyearling fish (Rip Shively, U.S. Geological Survey, Columbia River Research Laboratory, Cook, WA, 98605, Pers. commun., October 1998). Student's *t*-test distributions were used to evaluate relative survival in relation to fork length. Paired *t*-tests were used for evaluating survival differences separated by site of detection (Bonneville Dam First Powerhouse, Bonneville Dam Second Powerhouse, the estuary off Jones Beach, and the bird colonies).

We tested the assumption of mixing between treatment and reference groups (i.e., homogeneity of passage distributions at Bonneville Dam) with chi-square tests for each release date, using a Monte Carlo approximation of the exact method to calculate P-values (Mehta and Patel 1992). Significance was established at $P \leq 0.05$. Relative survival estimates for groups identified as not mixed were compared to those of mixed groups using a two-sample *t*-test.

We evaluated whether differences among arrival times at Bonneville Dam might impart systematic differences to detection ratios of spillway (treatment) and tailrace (reference) fish passing via the first powerhouse, second powerhouse, or by inference, the spillway. For each day or night release, the proportion of reference fish and treatment fish passing hourly at the first or second powerhouses was compared to the hourly proportions of total powerhouse flow and total river flow. Average powerhouse flow percentages were then calculated for spillway (treatment) and tailrace (reference) groups and compared by paired *t*-test.

RESULTS

Spring Migration: Yearling Chinook and Coho Salmon

On test days 21 April-29 May, during hours of release, river flow ranged from 6,119 to 10,992 m³/second (216,000 to 388,000 ft³/second), and average spill ranged from 2,125 to 4,108 m³/second (75,000 to 145,000 ft³/second) during 30% spill and 4,023 to 5,949 m³/second (142,000 to 210,000 ft³/second) during 64% spill (Appendix Tables A1 and A2). Of the 139,078 PIT-tagged chinook and coho salmon released, 19.8% (27,474 unique tags) were detected at one or more downstream sites (Table 1; Appendix Table A5). Of 69,419 PIT-tagged salmon released as tailrace (reference) groups at a site downstream from the Highway 197 bridge, 20.3% (14,102 unique tags) were detected. Proportions of total PIT-tag detections from spring migrants were 18% at Bonneville Dam First Powerhouse, 61% at Bonneville Dam Second Powerhouse, 7% in the estuary off Jones Beach, and 14% from abandoned bird colonies in the estuary.

The PIT-tag detection data were separated by detection site to evaluate variability of relative survival estimates between sites. Average survival estimates for spillway passage calculated from detections at Bonneville Dam First Powerhouse (90%) were lower than those calculated from detections at Bonneville Dam Second Powerhouse (93%). They were also lower than estimates calculated from detections of the trawl off Jones Beach (99%) or detections from the bird colonies (106%)*. Survival estimates from detections at Bonneville Dam First and Second Powerhouse combined averaged 17% lower than those from detections on bird colonies. Statistical analyses of the separated data are presented in Appendix Table B1.

Paired *t*-tests of the natural log of relative survival ratios indicated no significant differences between treatment-to-reference survival ratios from Bonneville Dam First Powerhouse and those from Bonneville Dam Second Powerhouse ($P = 0.30$). Comparisons between combined detections from Bonneville Dam and those from the trawl off Jones Beach suggested a significant difference at $P = 0.19$, and comparisons between combined Bonneville Dam detections and those from bird colonies indicated a significant difference at $P < 0.01$. Finally, a paired *t*-test of the natural log of relative survival between detections measured at Jones Beach vs. those measured on abandoned bird colonies indicated a significant difference at $P = 0.08$. We utilized the combined data from all recovery sites for all further analyses.

* When true survival probabilities are close to 100% or when sampling variability is high, it is possible for survival probabilities to exceed 100%. For practical purposes, estimates should be considered equal to 100% in these cases (Steven G. Smith, NMFS, Pers. commun., November 1998).

Table 1. Numbers and percentages of PIT-tagged fish released and detected at various locations by treatment and condition for The Dalles survival study in 1999.

Conditions	Releases		PIT-tag detections by location					Total*	Detect (%)*
	Site	No.	Bon. 1	Bon. 2	Jones B.	Bird Col.	Total*

* Total observed (used for combined analysis) is the number of unique tags observed at any of the sites. Multiple observations of a tag are not counted. Numbers observed at individual sites may include tags observed at other sites, and these data were used to make the inter-site comparisons.

Survival Estimates

Survival for spillway-released coho and spring chinook salmon combined (spring migration) at both 64 and 30% spill was significantly different (lower) from survival of reference fish released downstream from the dam. The point estimate (unweighted geometric mean for all release periods) of relative survival at 64% spill was 93.4% with a 95% confidence interval (CI) of 90.0-97.0%; and at 30% spill was 96.2% (CI 90.2-100.5%; Table 2).

Survival at 30% spill was not significantly different from survival at 64% spill ($P = 0.26$; Appendix Table B1). Relative survival percentages of daily releases ranged from 78.3 to 115.2%. These point estimates represent passage survival of mixed fish stocks throughout the migration period; during daytime (adult) and nighttime (juvenile) spill patterns; through spillbays across the width of the spillway; and at ambient spill-gate openings, river flows, tailwater elevations, and water temperatures.

The experimental design provided numbers of spring test fish sufficient to assess probable relative survival differences between treatment and reference groups at 30 and 64% spill, but these numbers were not sufficient to fully evaluate survival effects related to other controlled and uncontrolled variables. However, we examined the data for survival trends related to other variables.

There was a trend of increased survival through the period of testing ($P = 0.04$; Fig. 2; Appendix Table B1). Differences between spillway release location (north, middle, or south) were not significant ($P = 0.91$; Appendix Table B1). Nighttime spillway passage produced higher relative survival than daytime spillway passage ($P < 0.01$): mean spillway passage survival was 87.6 and 102.6% for daytime and nighttime releases, respectively. These daytime/nighttime differences were observed in data from both 30 and 64% spill conditions (Appendix Table B1). Additionally, relative survival was not strongly correlated to change in river flow, spill flow, water temperature, or tailwater elevation ($r = 0.15, -0.04, 0.14$, and 0.02 , respectively; Figs. 3a and 3b).

In addition to these analyses, we calculated survival and looked for trends and relationships in the data from coho and yearling chinook salmon separately. Relative survival proportions for coho salmon were similar to those for chinook salmon (Appendix Tables A6, A7, and B2). A paired *t*-test comparing survival estimates between these species found no significant difference ($P = 0.98$).

Test-fish body size at release was also evaluated as a variable affecting survival. We examined fork-length distributions of daily release groups separated into two fork-length categories: 125 mm or less and greater than 125 mm. Of the 20,842 fish measured at John Day Dam, 94% were large enough to be radio tagged (> 125 mm), while only 6% were too small to radio tag (Fig. 4). Detections from Bonneville Dam and those from the estuary (Jones Beach and bird colonies combined) showed no significant differences by fish size at release ($P = 0.09$ and 0.44 , respectively; Appendix Table B3).

Variability Associated with the Experimental Process

To assess differences in temporal distribution among treatment groups (mixing), we compared travel time and daily detection distributions at Bonneville Dam for daily release groups.

Travel time—The simplest method to evaluate whether mixing occurred among treatment groups was to assess travel time differences between treatment groups released during the same time period. Travel times through the 75-km river reach from The Dalles Dam to Bonneville Dam averaged about 1.8 days, with 80% of detections occurring within 2.1 days of release (Appendix Table B4). Travel time generally decreased through the test period ($r = -0.76$), and river flow did not appear to affect travel time ($r = -0.21$; Fig. 5). Travel time averaged 1.7 days for daytime releases and 1.9 days for nighttime releases; the difference was not significant ($P = 0.16$).

Mean travel times for tailrace-released reference groups averaged 0.2 days (5 hours) less than for spillway groups; the difference was significant ($P < 0.01$; Appendix Table B4). We have no explanation for the differences in travel time to Bonneville Dam, considering that spillway and tailrace fish appeared to exit the tailrace of The Dalles Dam at about the same time, as measured by radiotelemetry data (Theresa Liedtke, U.S. Geological Survey, Columbia River Research Laboratory, 5501A Cook Underwood Rd., Cook, WA 98605, Pers. commun., July 1999).

Temporal detection distributions—The homogeneity of passage distributions at Bonneville Dam (detection through time) for corresponding spillway- and tailrace-released groups of chinook and coho salmon suggested many violations of the mixing assumption. We used a chi-square test to compare passage distribution between tailrace and spillway releases of spring migrants from all 32 release periods. These tests indicated temporal differences in passage distribution at Bonneville Dam for 17 of the 32 periods (Appendix Table B5). Although the statistical analysis indicated that these arrival timing differences were significant, overall passage distributions for both the spillway and tailrace groups were quite compact, with spillway releases arriving only slightly later than tailrace releases.

To assess the importance of distribution differences, we compared the number of fish detected from spillway- and tailrace-release groups in relation to river flow and Bonneville Dam powerhouse operation. For each release period, hourly fish counts at the first or second powerhouse and the percentages of powerhouse flow, in relation to total powerhouse flow or total river flow at the time of passage, were calculated for treatment fish and reference fish separately. For each release period, the average flow percentage/fish for treatment and for reference fish was compared (Appendix Table B6). Differences between treatment and reference groups appeared negligible, averaging 0.0% for total powerhouse flow/fish and 0.1% for total river flow/fish in detections at the first powerhouse and 0.4% for total powerhouse flow/fish and 0.4% total river flow/fish in detections at the second powerhouse.

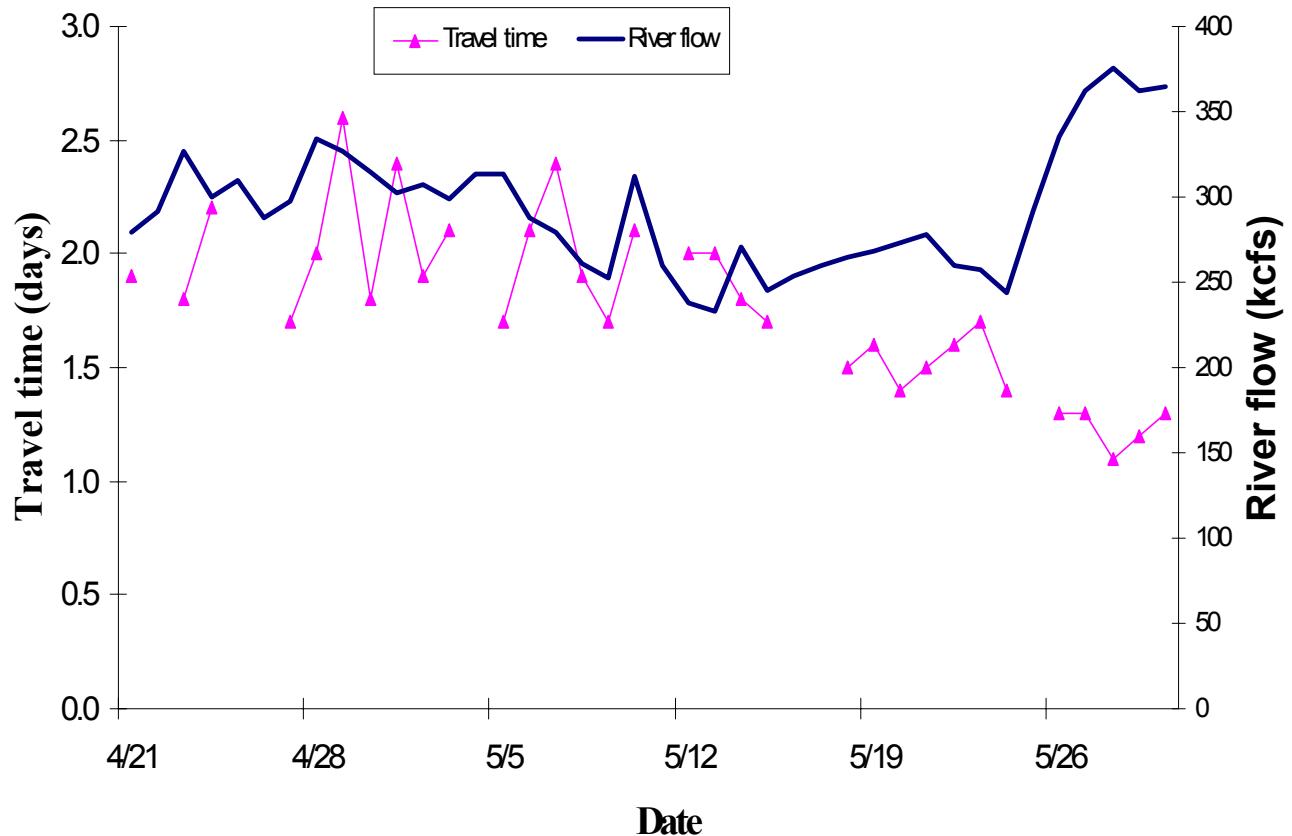

Figure 5. Travel time from The Dalles Dam to Bonneville Dam for daily release groups of spring test fish compared to average river flow, 1999.

Comparison with 1997 and 1998 Results and Trends for Combined Data

Detection site differences—Estimates of relative survival measured at Jones Beach and the bird colonies were compromised by low numbers of detections and resultant high variability among the daily releases (Appendix Table B1, B7, B8, and B9). Survival estimates measured at Bonneville Dam First Powerhouse averaged 2 and 5% higher (non-significant) and 3% lower than estimates measured at Bonneville Dam Second Powerhouse in 1997, 1998 and 1999, respectively. Estimates at Bonneville Dam (combined) were 0 to 19% lower (significant in two of three years) than at the bird colonies. Estimates measured at Jones Beach were 12 to 14% lower than at the bird colonies (significant in one year) and 14% lower than at Bonneville Dam in 1998, but 7% higher in 1999 (non-significant).

In general, estimates at all sites through all years showed greater survival at 30% spill than at 64% spill and greater survival for spillway passage at night with the juvenile spill pattern than during day with the adult spill pattern (Appendix Table B7).

Survival trends—The point estimate for spillway passage survival at 64% spill in 1999 (93%) was higher than in 1998 and 1997 (89 and 87%, respectively). Survival trend lines for 64% spill showed a slight increase through time in 1999, whereas in 1998 and 1997, they showed decreases through time (Fig. 6). The point estimate for spillway passage survival at 30% spill in 1999 (95%) was similar to that in 1998 (97%), but the trend line for spillway passage survival at 30% spill increased through the test period in 1999 but decreased through the test period in 1998 (Fig. 6).

ANOVA of combined 1997, 1998, and 1999 data indicated a significant difference in relative passage survival between 64 and 30% spill ($P = < 0.01$) and between daytime and nighttime releases ($P = 0.04$). Relative survival means were 88.9% at 64% spill and 98.1% at 30% spill. Relative survival means for daytime releases were 86.7 and 93.9% at 64 and 30% spill rates, respectively. These rates were significantly lower than those of nighttime releases, which were 91.2 and 102.5% for 64 and 30% spill levels, respectively ($P = 0.04$; Appendix Table B10).

Because comparisons between high and moderate spill rates were not conducted in 1997, we analyzed the combined data from 1998 and 1999 only. These data indicated a significant difference in relative survival between 64 and 30% spill ($P = 0.05$) and between daytime and nighttime releases ($P = 0.02$). Mean relative survival was 92.0% at 64% spill and 98.0% at 30% spill. Respective mean relative survival at 64 and 30% spill was 89.0 and 93.8% for daytime releases and 95.1 and 102.4% for nighttime releases (Appendix Table B11).

Travel times—Travel times to Bonneville Dam for tailrace (reference) groups were slightly less than those of corresponding spillway (treatment) groups. In 1999, travel times between treatment and reference groups were significantly different ($P < 0.01$); whereas in 1997 and 1998, differences were not significant ($P = 0.22$).

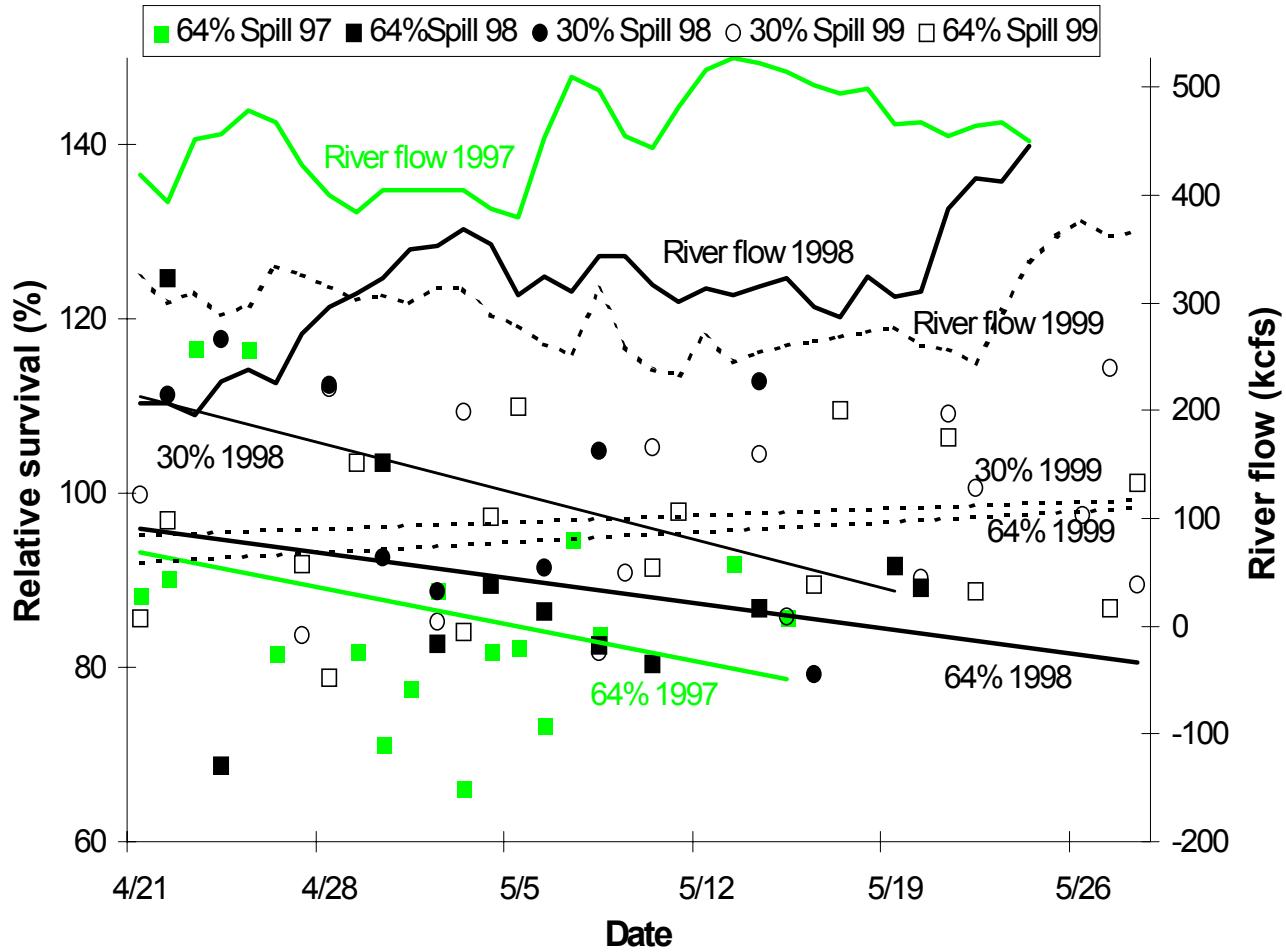

Figure 6. Relative spillway passage survival of yearling chinook and coho salmon and river flow at The Dalles Dam through the period of testing, 1997, 1998, and 1999.

Uncontrolled variables—Evaluations of survival in relation to the following individual dependent variables showed poor correlation in springtime tests using yearling chinook and coho salmon: water temperature, spill flow, river flow, and tailwater elevation ($r = 0.04, -0.21, -0.08$, and -0.13 , respectively; Figs. 7a and 7b). Stepwise regression of dependent variables, excluding spillbay location, provided poor predictive capability utilizing data from either individual years or multiple years; for 1997-1999 combined data ($R^2 = 0.15$; Appendix Table B12).

Powerhouse operations—Examination of the data on powerhouse operations for each of the 3 years of study showed that differences at Bonneville Dam during passage between tailrace- and spillway-released groups appeared to be minor with no notable trends between years. Average river flows per fish and average powerhouse flows per fish showed no discernable pattern at either powerhouse for any of the treatments (Appendix Tables B6, B13, and B14).

Upstream gull colonies—Land-based PIT-tag surveys of the gull colonies upstream from The Dalles Dam (Little Memaloose and Little Miller Islands) detected approximately 0.2% of all tags from spring migrants released in 1997 and 1998 and 0.08% of all tags from spring migrants released in 1999. It is interesting to note that of the records from these islands, tags from spillway-released (treatment) fish comprised 90% of the detections in 1997 and 1998 and 84% of the detections in 1999 (Brad Ryan, NMFS, P.O. Box 155, Hammond, OR 97121, Pers. commun., February 2000). Nevertheless, the total proportion of tags detected at these colonies was minimal, and the proportion that may have been dropped at other locations is unknown.

Summer Migration: Subyearling Chinook Salmon

On test days 17 June to 19 July during hours of release, river flow ranged from 6,261 to 10,453 m³/second (221,000 to 369,000 ft³/second); average spill ranged from 2,040 to 2,975 m³/second (72,000 to 105,000 ft³/second) during 30% spill and 3,966 to 5,949 m³/second (140,000 to 210,000 ft³/second) during 64% spill (Appendix Tables A3 and A4). Of the 166,727 PIT-tagged subyearling chinook salmon released, 13.6% (22,675 unique tags) were detected at one or more downstream sites (Table 1; Appendix Table A8). Of the 83,361 PIT-tagged subyearling chinook salmon released at the reference location just downstream from the Highway 197 bridge, 13.8% (11,491 unique tags) were detected.

Respective proportions of PIT-tag detections at Bonneville Dam First Powerhouse, Second Powerhouse, and bird colonies were about 15, 74, and 11% of total detections during the summer migration. (Sampling with the detector trawl off Jones Beach was not conducted during the summer migration.) PIT-tag detection data were separated by detection site to evaluate relative survival differences between sites. Average survival estimates from detections at Bonneville Dam First Powerhouse were lower than those from detections at Bonneville Dam Second Powerhouse or the bird colonies (92, 99, and 104%, respectively). Survival estimates for detections at Bonneville Dam (first and second powerhouse combined) averaged 8% lower than those for detections on the bird colonies. Statistical analyses of the separated data are presented in Appendix Table B15.

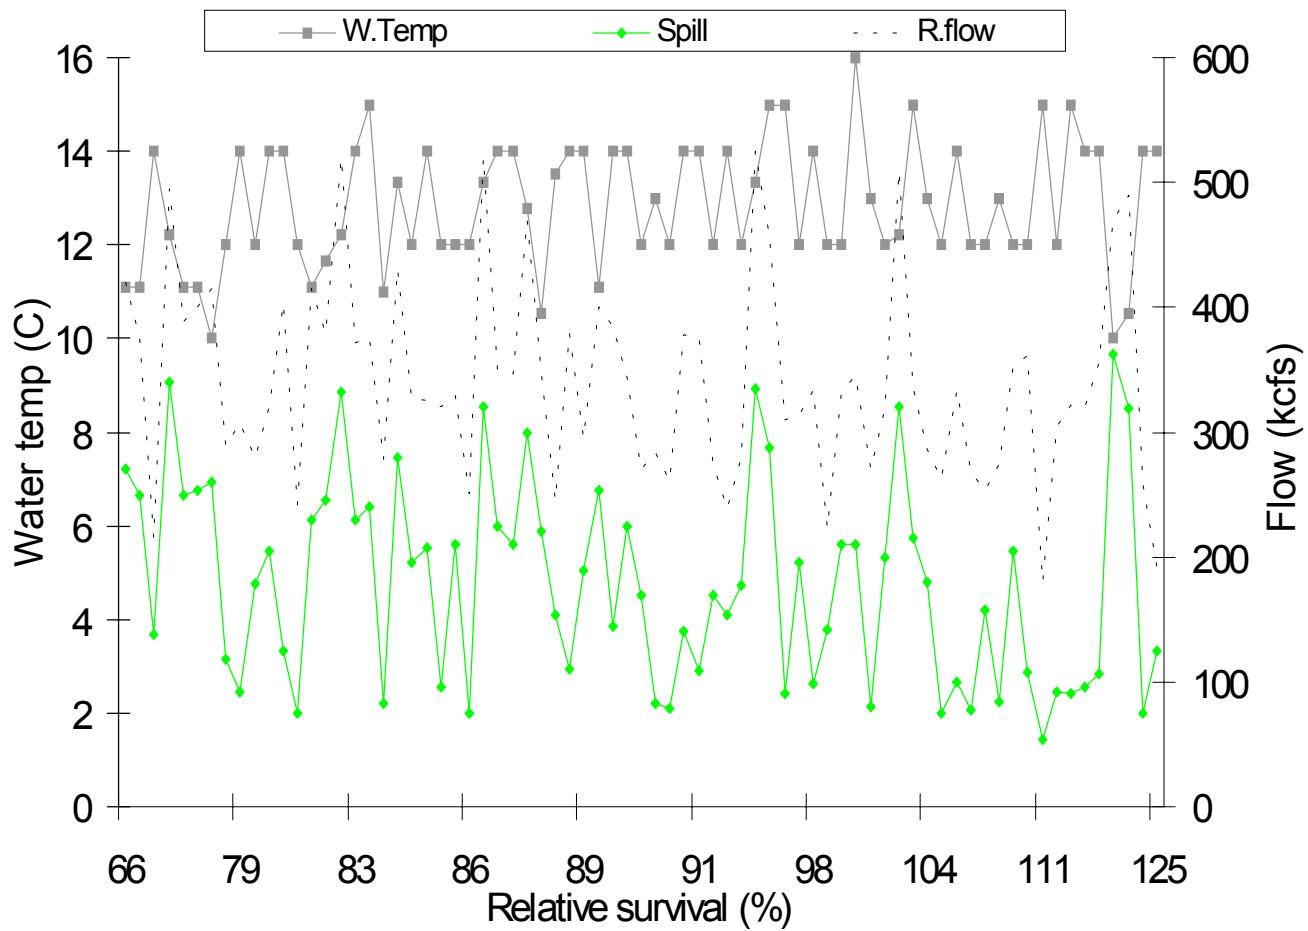

Figure 7a. Relative survival of spring migrating test fish in relation to water temperature, spill volume, and river flow at The Dalles Dam, 1997, 1998, and 1999.

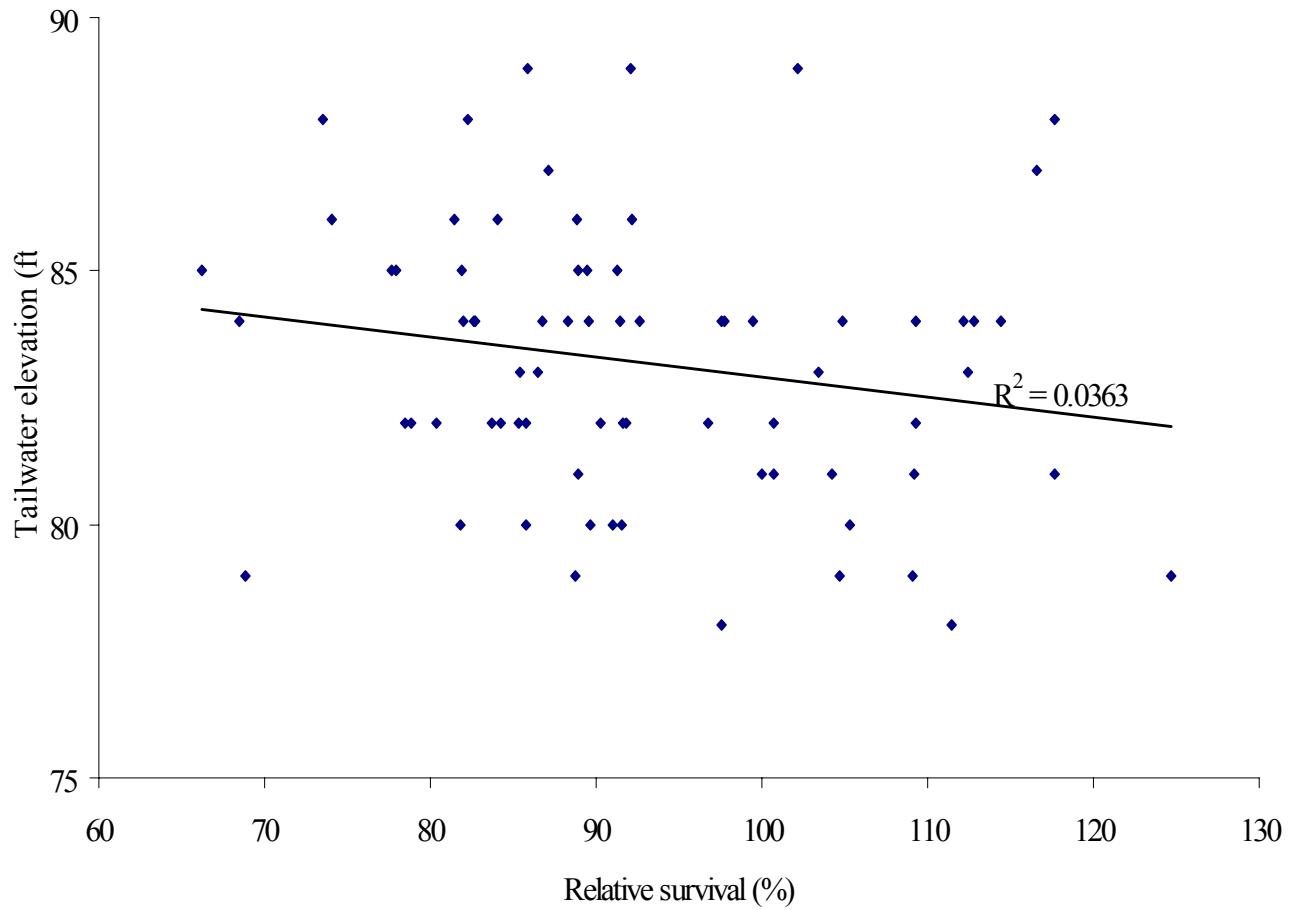

Figure 7b. Relative survival of spring migrating test fish in relation to tailwater elevation at The Dalles Dam, 1997, 1998, and 1999.

Paired *t*-tests were used to compare the natural log of relative survival estimates by PIT-tag detection location and method. These tests indicated a significant difference in relative survival estimates calculated from bypass-system detections at Bonneville Dam First Powerhouse vs. those calculated from bypass-system detections at Bonneville Dam Second Powerhouse ($P = 0.02$; Appendix Table B5). Comparison of survival estimates calculated from combined detections at Bonneville Dam vs. those calculated from land-based detections at piscivorous bird colonies indicated no significant difference ($P = 0.36$). We utilized combined data from all recovery sites for all other analyses.

Survival Estimates

Survival at 64% spill for spillway-released (treatment) subyearling chinook salmon was significantly lower than that for tailrace-released (reference) cohorts; whereas survival at 30% spill was not significantly different between treatment and reference fish. The point estimate (unweighted geometric mean for all release periods) of relative survival was 95.9% at 64% spill (CI = 92.3-99.6%), and 99.5% at 30% spill (CI = 94.9-104.3%; Table 3). These point estimates represent passage survival of mixed fish stocks throughout the migration period; during day and night; through spillbays across the width of the spillway; and at ambient spill-gate openings, river flows, tailwater elevations, and water temperatures. Survival at 64% spill was not significantly different (lower) than survival at 30% spill ($P = 0.20$; Appendix Table B15). Relative survival percentages calculated for daily releases ranged from 80.7 to 121.7%.

The experimental design provided sufficient numbers of test fish to assess probable relative survival differences between spillway (treatment) and tailrace (reference) groups at 30 and 64% spill during summer tests. We examined the data for survival trends or relationships with other controlled and uncontrolled variables; however, the numbers of test fish were not sufficient for these evaluations.

Differences in passage survival between spillway release locations were not significant ($P = 0.97$; Appendix Table B15). Through the period of testing there appeared to be a trend of decreasing survival at 30% spill but a trend of increasing survival at 64% spill (Fig. 8). Nighttime spillway passage produced higher relative survival than daytime spillway passage ($P = 0.02$). Mean relative survival was 94.3% for daytime passage and 101.2% for nighttime passage, and these differences were greater at 30% spill than at 64% spill (Appendix Table B15). We saw no strong correlations between relative survival and changes in river flow, spill flow, tailwater elevation, or water temperature ($r = 0.27, -0.05, 0.30$, and -0.05 respectively; Figs. 9a and 9b).

Test-fish body size at release was evaluated as a variable affecting survival. We examined fork-length distributions of daily release groups separated into two fork-length categories: 110 mm or less and greater than 110 mm. Of the 17,040 fish measured at John Day Dam, 37% were large enough to be radio tagged (>110 mm), while 63% were too small (Fig. 10). Combined detections from Bonneville Dam showed that a significantly higher proportion of larger fish were detected ($P = 0.01$), as did combined data from the piscivorous bird colonies and the trawl off Jones Beach ($P = 0.01$; Appendix Table B16).

Variability Associated with the Experimental Process

To assess differences in temporal distribution between treatment and reference groups (mixing), we compared travel times over the 75-km reach from the release sites to Bonneville Dam as well as daily detection distributions at Bonneville Dam.

Travel times—The simplest method to evaluate whether mixing occurred among treatment groups was to assess travel time differences between treatment and reference groups released during the same time period. Travel times through the 75-km river reach from The Dalles Dam to Bonneville Dam averaged about 1.7 days, with 80% of detections occurring within 1.9 days (Appendix Table B17). Travel times showed a slight increase through the test period ($r = 0.55$), a period of decreasing river flow ($r = -0.64$; Fig. 11). Daytime releases averaged 1.7 days to reach Bonneville Dam, and nighttime releases averaged 1.8 days; the difference was significant ($P = 0.05$).

Mean travel time of tailrace-released reference groups averaged 0.12 days (3 hours) less than that of spillway groups; the difference was significant ($P = 0.00$; Appendix Table B17). We have no explanation for the differences in travel time to Bonneville Dam, considering that spillway and tailrace fish exited the tailrace of The Dalles Dam at about the same time, as measured by radiotelemetry data (Theresa Liedtke, U.S. Geological Survey, Columbia River Research Laboratory, 5501A Cook Underwood Rd., Cook, WA 98605, Pers. commun., July 1999).

Temporal detection distributions—We evaluated the homogeneity of passage distributions at Bonneville Dam (PIT-tag detections through time) for corresponding spillway- and tailrace-released groups of subyearling chinook salmon. Using a chi-square test of the homogeneity of passage distributions we found significant differences in temporal distribution between spillway- and tailrace-release groups in 11 of 28 release periods (Appendix Table B5). However, in spite of statistical evidence that the two groups did not mix, passage distributions for both spillway and tailrace groups were quite compact, with spillway groups generally arriving slightly later.

To assess the biological importance of these distribution differences, we compared detections of fish from spillway- vs. tailrace-release groups in relation to powerhouse operation and river flow. For each release period, we calculated hourly fish counts at the first or second powerhouses, and the percentages of powerhouse flow and total river flow/fish at the time of passage for treatment fish vs. reference fish.

We then compared average flow percentages per fish by release period for treatment and reference fish (Appendix Table B18). The data indicated negligible differences in passage conditions between mixed and non-mixed groups. Results showed no difference in total powerhouse flows/fish and an average difference of 0.1% in total river flow/fish between tailrace- and spillway-release groups detected at the first powerhouse. For groups detected at the second powerhouse, we found an average difference of -0.1% in powerhouse flow/fish and -0.1% in total river flow/fish between tailrace- and spillway-release groups.

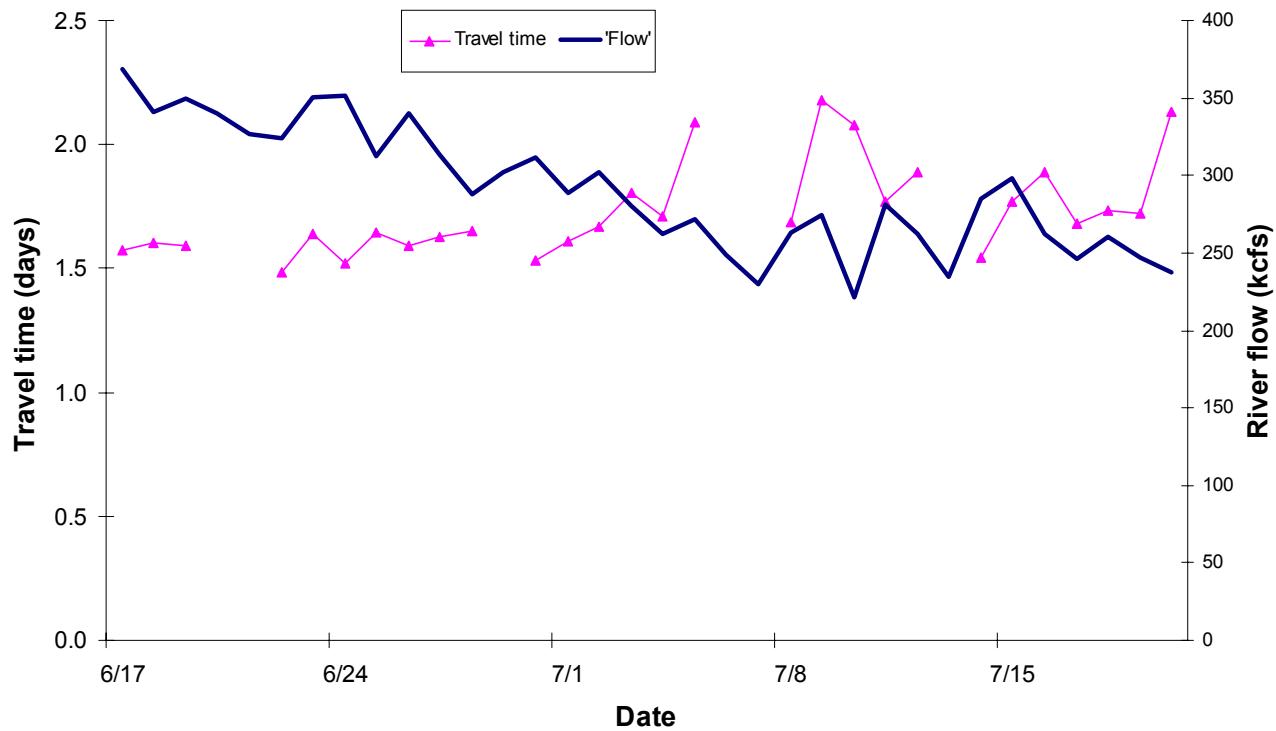

Figure 11. Travel time from The Dalles Dam to Bonneville Dam for daily release groups of summer test fish compared to average river flow, 1999.

Comparison with 1997 and 1998 Results and Trends for Combined Data

Detection site differences—Estimates based on detections at the bird colonies were compromised by low numbers of detections and resultant high variability among daily releases (Appendix Tables B7, B8, B9, and B15). Survival estimates measured at Bonneville Dam First Powerhouse were 3 to 5% lower (significant in two of three years) than estimates measured at Bonneville Dam Second Powerhouse. Estimates at Bonneville Dam (combined) were 5 to 26% lower (significant in two of three years) than at the bird colonies.

In general, estimates at all sites through all years showed greater survival at 30% spill than at 64% spill and greater survival for spillway passage at night with the juvenile spill pattern than during day with the adult spill pattern.

Survival trends—The point estimate for passage survival at 64% spill in 1999 (96%) was higher than those in 1998 and 1997 (75 and 92%, respectively). Survival trend lines at 64% spill showed a decrease through time during 1997 and 1998, but a slight increase during 1999 (Fig. 12). The point estimate for passage survival at 30% spill in 1999 was substantially higher than in 1998 (100 and 89%, respectively). In 1999 and 1998, survival at 30% spill decreased through the test period (Fig. 12).

ANOVAs of combined 1997, 1998, and 1999 data indicated significant differences in relative survival between 64 and 30% spill ($P = 0.04$) and between daytime and nighttime releases ($P < 0.01$). Relative survival means were 88.2% at 64% spill and 96.0% at 30% spill. Relative survival means for daytime releases at 64 and 30% spill (84.8 and 87.8%, respectively) were lower ($P = < 0.01$) than for nighttime releases (91.8 and 105.1%, respectively; Appendix Table B10).

Because comparisons between 64 and 30% spill rates were not conducted in 1997, we analyzed the combined data from 1998 and 1999 only. These data indicated significant differences in relative survival between 64 and 30% spill ($P = 0.04$) and between daytime and nighttime releases ($P = 0.02$). Relative survival means were 86.4% at 64% spill and 95.4% at 30% spill. Respective relative survival means at 64 and 30% spill were 83.8 and 87.2% for daytime releases and 89.1 and 104.4% for nighttime releases (Appendix Table B11).

Travel times—Travel times to Bonneville Dam for groups of tailrace-released subyearling chinook salmon were slightly less than those of their spillway-released cohorts in all three years, with differences of 0.3, 0.1, and 0.1 days in 1997, 1998, and 1999, respectively (Appendix Table B17).

Uncontrolled variables—Evaluations of relative survival estimates for subyearling chinook summer migrants showed poor correlation with the following individual dependent variables: water temperature, spill flow, river flow, and tailwater elevation ($r = -0.49, 0.08, 0.44$, and 0.44 respectively; Figs. 13a and 13b). Linear regressions of dependent variables including Julian date provided poor predictive capability, whether analyses were based on individual or multiple years (e.g., for 1997-1999 combined data, $R^2 = 0.32$; Appendix Table B19).

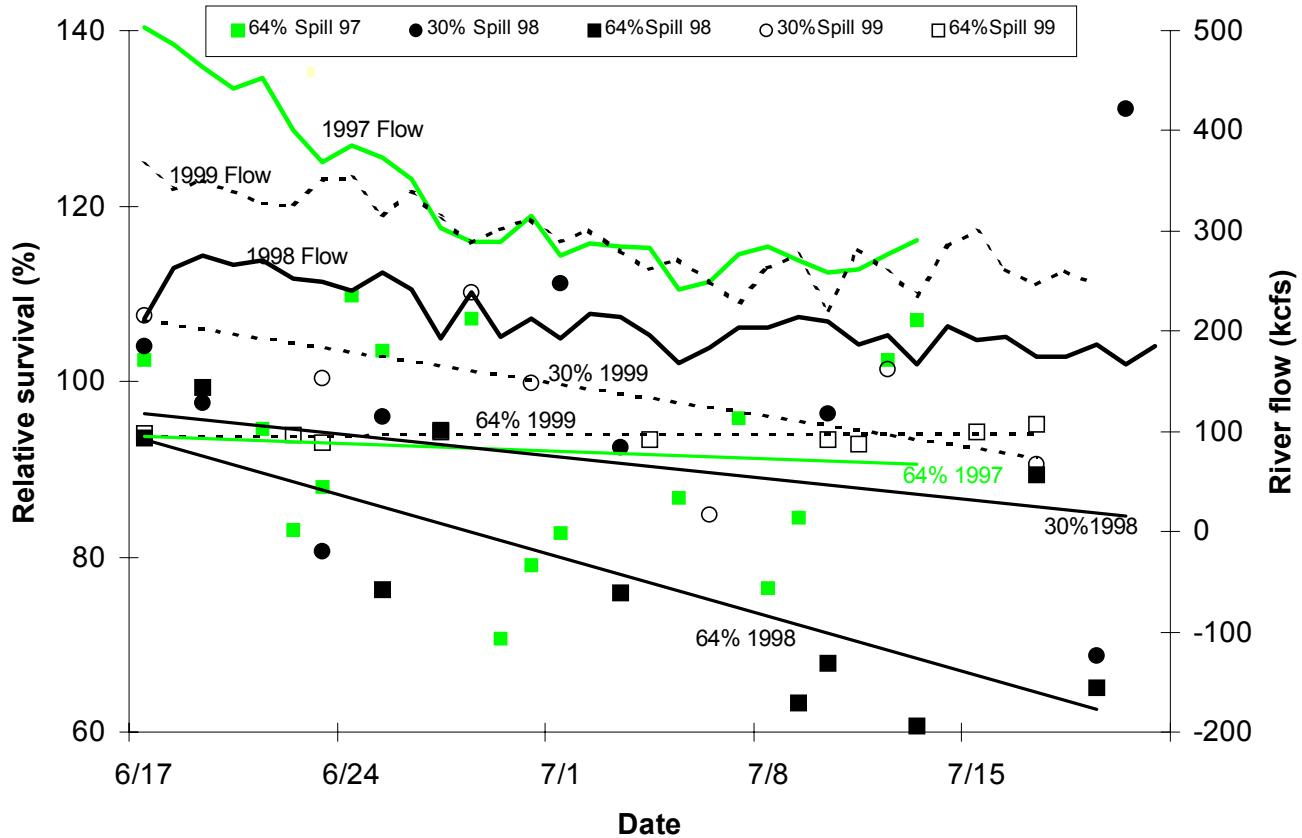

Figure 12. Relative spillway passage survival of subyearling chinook salmon at The Dalles Dam through the period of testing, 1997, 1998, and 1999.

Powerhouse operations—Examination of the data on powerhouse operations for each of the three years of study showed that differences during passage at Bonneville Dam appeared to be minor, with no discernable trends for either tailrace- or spillway-released fish groups. Variation in average flows per fish appeared to be random in both direction and magnitude at both Bonneville Dam powerhouses for all daily release groups (Appendix Tables B13, B14, and B18).

Upstream gull colonies—Land-based PIT-tag surveys of the gull colonies upstream from The Dalles Dam (Little Memaloose and Little Miller Islands) detected approximately 0.05% of all tags from summer migrants released in 1997 and 1998 and 0.06% of all tags from summer migrants released in 1999. It is interesting to note that of the records from these islands, tags from spillway-released (treatment) fish comprised 90% of the detections in all three years (Brad Ryan, NMFS, P.O. Box 155, Hammond, OR 97121, Pers. commun., February 2000). The total proportion of tags detected at these colonies was minimal, and the proportion that may have been dropped at other locations is unknown.

DISCUSSION

We found that average survival estimates differed in relation to whether detections from Bonneville Dam, Jones Beach, or the piscivorous bird colonies were used in the analyses. These differences were not surprising because Bonneville Dam, the Jones Beach pair-trawl, and bird colonies on estuarine islands each utilized different sample mechanisms (guidance screen, towed trawl net, and bird feeding behavior) and each was subject to sampling bias associated with that mechanism.

We speculate that differences in detection probabilities between the two powerhouses at Bonneville Dam could be related to poor spatial mixing of reference and treatment fish groups, with fish staying oriented to the side of the river on which they were released. For example, survival estimates would be higher at the first powerhouse and lower at the second powerhouse if treatment-fish detections were more likely at the first powerhouse and reference-fish detections were more likely at the second powerhouse. This pattern was in fact observed in spring but not in summer tests in 1999 (or in all three years).

Additional differences in detection-rate probabilities between treatment and reference groups may have been related to diel changes in test-fish depth distribution at Bonneville Dam coupled with arrival time differences. Survival estimates based on PIT-tag detections from bird colonies in particular are influenced by whether the treatment and reference groups were completely mixed (pass the islands at the same time and at the same depth) and by hourly variation in the foraging behavior of avian predators.

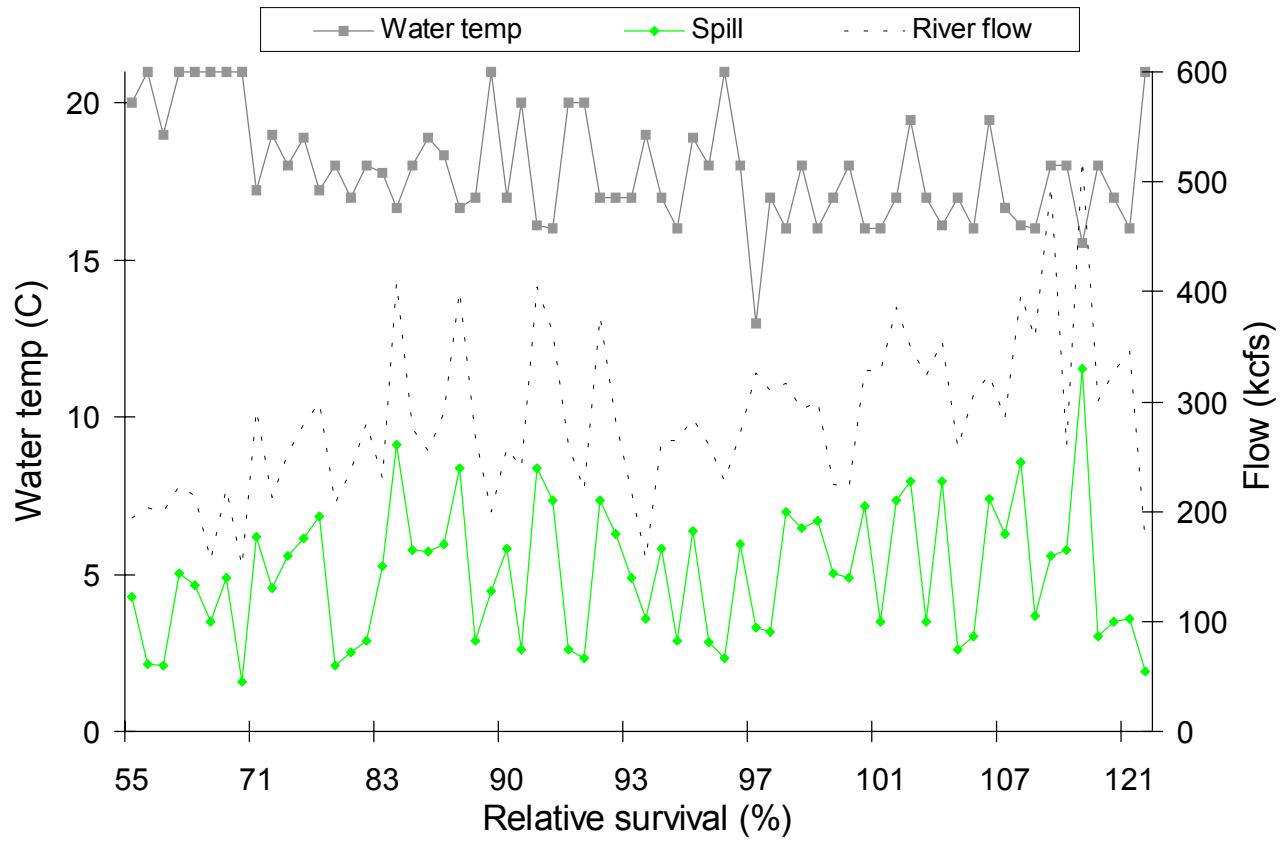

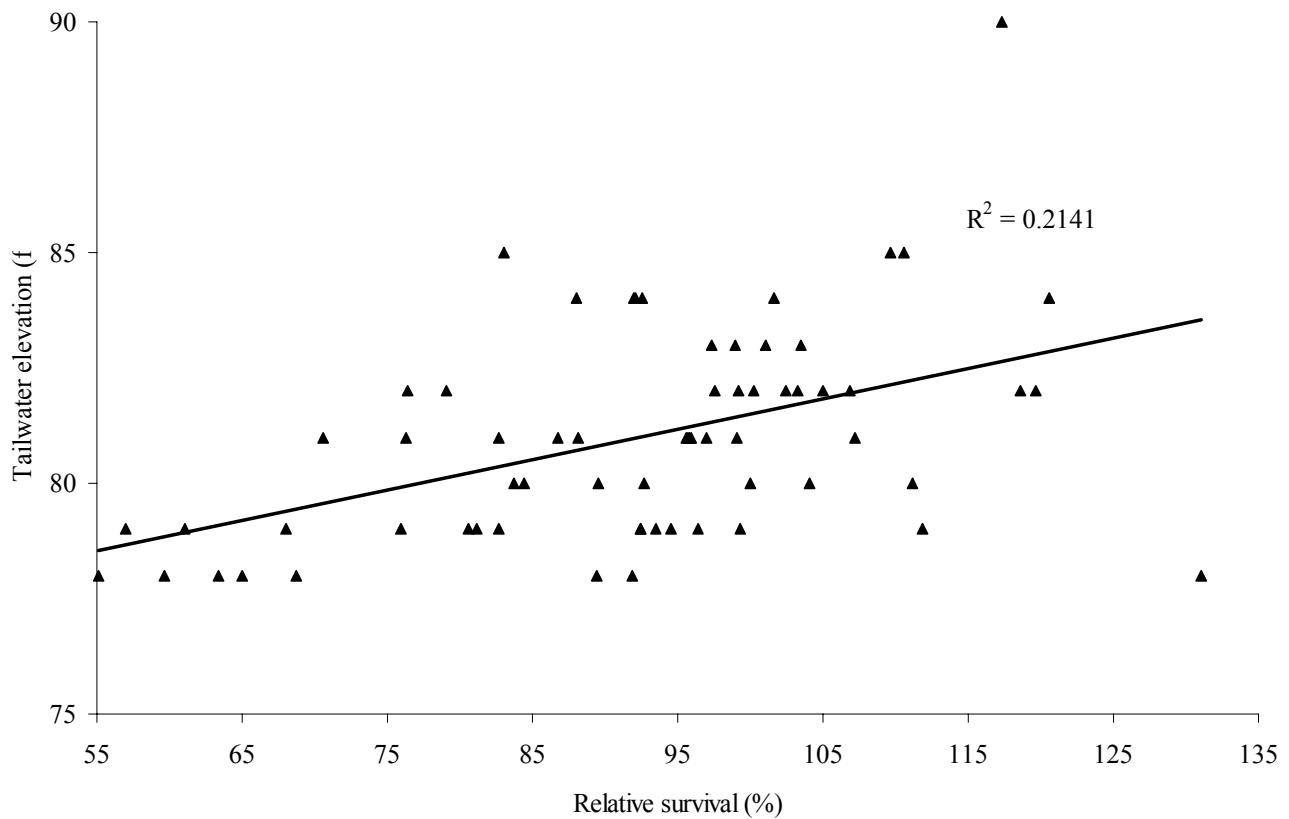

Figure 13a. Relative survival of summer migrating test fish in relation to water temperature, spill volume, and river flow at The Dalles Dam; 1997, 1998, and 1999.

In summary, survival estimates based on detections at Bonneville Dam were generally lower than those based on detections at other sites. However, in estimates based on recoveries at all sites, comparisons between 30 and 64% spill and between day and night releases generally trended in the same direction, with detections of fish released at 30% spill and during nighttime hours consistently producing the highest relative survival estimates.

Based on our initial evaluation of the data on powerhouse operations, defined in terms of the ratios between average river flow per fish and average powerhouse flow per fish, we believe that hourly powerhouse operations at Bonneville Dam had no systematic affect on our estimates. Variations in these ratios were minor, with no notable trends within or among the three years; thus we concluded that valid estimates could be derived using combined data from all detection sites. During the study period for all three years, spring flows ranged from 5,549 to 15,763 m³/second (196,000 to 557,000 ft³/second) and summer flows ranged from 4,726 to 14,235 m³/second (167,000 to 503,000 ft³/second).

The passage survival results related to operations at The Dalles Dam were as follows:

- 1) Detection rates of fish passing through the spillway at 64% spill were significantly less than those of their cohorts released downstream from the dam (Table 4).
- 2) In the two years of direct comparison, point estimates for relative survival of fish passing at 64% spill were lower (but not significantly different) than those of fish passing at 30% spill. When annual data from 1998 and 1999 were combined for analysis, differences between spill rates were significant for spring migrants ($P = 0.05$) and for summer migrants ($P = 0.04$). Respective point estimates for passage survival at 64 and 30% spill were 92.0 and 98.0% for spring migrants and 86.4 and 95.4% for summer migrants.
- 3) Analyses from three years of data show that spillway passage during daytime hours (adult spill patterns) produced lower survival estimates than spillway passage during nighttime hours (juvenile spill patterns), with daytime/nighttime survival estimates of 90.2 vs. 96.7% ($P = 0.04$) for spring migrants and 86.3 vs. 98.2% ($P = < 0.01$) for summer migrants.
- 4) Comparisons from two years of data indicate that survival estimates for juvenile salmon passing the spillway at The Dalles Dam under 64% spill are lower than estimates for juvenile spillway passage at other dams, and are similar to or lower than survival estimates for turbine passage (NMFS 2000).
- 5) Data from one year of testing (1998) showed that relative survival estimates for daytime fish passage through the sluiceway were similar to those of daytime fish passage through the spillway at 30% spill.
- 6) For both spring and summer migrants, evaluations of relative survival in relation to tailwater elevation, spill volume, river flow, and water temperature indicated poor correlations.

Table 4. River flow and point estimates with 95% confidence intervals for relative passage survival of juvenile salmon at The Dalles Dam, 1997, 1998, and 1999.

Year	River flow (kcfs)		64% Spill		30% Spill	
	Median	Range	Spillway survival, % (95% CI)	Spillway survival, % (95% CI)	Sluiceway survival, % (95% CI)	
Spring migration (coho or chinook and coho salmon)						
1997	455	379-557	87 (80-94)			
1998	347	196-445	89 (82-95)	97 (88-107)	96 (87 -105)	
1999	273	239-376	93 (90 -97)	96 (92-101)		
Summer migration (subyearling chinook salmon)						
1997	301	213-503	92 (86-99)			
1998	212	167-279	75 (68-83)	89 (80-99)	89 (81-98)	
1999	300	221-369	96 (92 -100)	100 (95-104)		

RECOMMENDATIONS

The following are recommendations for research in 2000:

- 1) Evaluate a single, constant spill rate at less than 64% with juvenile spill patterns during 24 hours/day and include sluiceway- and turbine-passage survival. Maximum fish numbers should be used to obtain the highest possible statistical sensitivity.
- 2) Continue evaluations that include detection data from PIT tags deposited in estuarine and lower-river bird colonies to provide increased detection numbers.
- 3) Continue assessment of differences between detection sites and evaluate combined data from 1997, 1998, 1999, and future years.
- 4) Minimize operations of the sluice chute at Bonneville Dam Second Powerhouse to maximize the PIT-tags detected at Bonneville Dam.

ACKNOWLEDGMENTS

We wish to express our appreciation to those who participated in this research. COE personnel, especially Robert Dach for collaboration with development of the experimental design and resolution of strategic problems and Marvin Shutters, Steven Dingman, and Miroslaw Zyndol for their assistance with the regional coordination and project operations and coordination at The Dalles Dam. The NMFS personnel supervised by Rick Martinson were invaluable in operation of the smolt separator and holding system at John Day Dam and the PIT-tag detection systems at Bonneville Dam. Without their efforts the study would not have been successful.

^a Total (used for combined analysis) is the number of unique tags observed at any of the sites. Multiple observations of a tag are not counted. Numbers observed at individual sites may include tags observed at other sites, and these data are used to make the inter-site comparisons.

Appendix Table A6. Detections numbers, and survival percents for chinook salmon at each site, separated by passage condition at release; spring 1999.

^a Total (used for combined analysis) is the number of unique tags observed at any of the sites. Multiple observations of a tag are not counted. Numbers observed at individual sites may include tags observed at other sites, and these data are used to make the inter-site comparisons.

Appendix Table A7. Detection numbers, and survival percentages for coho salmon at each site, separated by passage condition at release; The Dalles Dam, spring 1999.

^a Total (used for combined analysis) is the number of unique tags observed at any of the sites. Multiple observations of a tag are not counted. Numbers observed at individual sites may include tags observed at other sites, and these data are used to make the inter-site comparisons.

Appendix Table A8. Detection numbers, and survival percents for subyearling chinook salmon at each site, separated by passage condition at release; summer 1999.

* Total (used for combined analysis) is the number of unique tags observed at any of the sites. Multiple observations of a tag are not counted. Numbers observed at individual sites may include tags observed at other sites, and these data are used to make the inter-site comparisons.

APPENDIX B

Statistical Analyses of Pit-Tag Interrogation Data, Fork Length Data, and Passage-Condition Data in Relation to Relative Survival for The Dalles Dam Juvenile Passage Survival Study, 1999

Appendix Table B1. Means, Confidence Intervals (CI), *t*-tests, and Analysis of Variance for PIT-tag interrogations of The Dalles Dam passage survival study for spring migrating juvenile salmon at Bonneville Dam, Jones Beach, bird colonies, and combined data, 1999.

^a No significant difference in travel time was detected for north vs. middle vs. south released spillway groups. Mean travel time of spillway groups was significantly different from tailrace released groups (spill group averaged 0.21 day longer at Bonneville and 0.17 day longer at Jones Beach; P < 0.01 and < 0.01, respectively). Mean travel time for fish groups detected at Bonneville First Powerhouse was significantly different from those detected at Bonneville Second Powerhouse (P < 0.01; PH 1 averaged 0.11 day longer). Mean travel time for nighttime releases was not significantly different from daytime releases (P = 0.16; nighttime releases averaged 0.18 day longer).

^b Average travel time to Bonneville Dam decreased through time, r = -0.76.

^c River flow in thousand ft³/second by COE convention; 1,000 ft³/second = 28.3 m³/second. Average travel time to Bonneville Dam was poorly correlated with river flow, r = -0.21.

Appendix Table B5. Tests of homogeneity of Bonneville Dam passage distributions for groups of PIT-tagged yearling chinook and coho salmon and subyearling chinook salmon released into the spillway or tailrace at The Dalles Dam in 1999.

H_0 : For spillway and tailrace releases made concurrently at The Dalles Dam, there was no difference in passage distributions at Bonneville Dam.^a

Yearling Chinook and Coho salmon				Subyearling chinook salmon

^a Comparing dates of arrival at Bonneville Dam among treatment groups.

^b The second occurrence of a date implies two morning /evening releases were made.

^c Probability values were calculated using a Monte Carlo approximation of the exact method.

^{d*} Indicates significant difference in passage distributions of spillway and tailrace released groups; however, passage distributions for both were quite compact (note the small number for degrees of freedom) with the spill group slightly later for yearlings (0.21 day) and slightly earlier for subyearlings (0.06 day).

Appendix Table B6. Comparisons of average of hourly fish counts multiplied by percent flow at Bonneville Dam First or Second Powerhouse, in relation to total turbine discharge or total river flow, for test fish released at The Dalles Dam Spillway or Tailrace, spring 1999.

^a Average of hourly data weighted by fish number for counts of fish detected at the designated powerhouse multiplied by percentage of designated powerhouse flow of the total powerhouse flow.

^b Average of hourly data weighted by fish number for counts of fish detected at the designated powerhouse multiplied by percentage of designated powerhouse flow of total river flow.

^c Spillway Fish x PH % of PH flow minus Tailrace Fish x PH % of PH flow.

^d Spillway Fish x PH % of Total flow minus Tailrace Fish x PH % of Total flow.

^e Index for spill percent (64 or 30) and day or night (D or N) for condition and period of fish releases at The Dalles Dam.

^f Indicates fish releases that were not mixed according to the Monte Carlo approximation of the exact method. A two-sample *t*-test was conducted on PH Difference and Total Difference for both Bonneville First and Second Powerhouses for fish releases that were not mixed compared to those that were mixed and there was no significant difference between them; P = 0.13-0.92.

* Probabilities of difference: Bon 1 vs. Bon 2 = 0.22; and Bon vs. Rice I. = 0.11. Detection numbers include duplicate recoveries of some fish, thus the sum of detections do not correspond with totals used for other evaluations.

Appendix Table B9. Release and detection data used to compare recovery sites; spring and summer 1998.

Correlation coefficient: $r = 0.04$ -0.21 -0.08 -0.13Linear regression $R^2 = 0.15$: $\ln \text{Surv } \% = -0.1357 -0.00054(\text{Spill kcfs}) + 0.100(\text{Diel index})$ ^a Correlations were not calculated for Julian date, Spill %, Diel index, and Spillbay location because of interaction, the best evaluation was to use ANOVA.^b Diel index, where 1 represents daytime releases and 2 represents nighttime releases.

Spillbay location where 1=North, 2=Middle and 3=South.

Appendix Table B13. Comparisons of average of hourly fish counts multiplied by percent flow at Bonneville Dam First or Second Powerhouse, in relation to total turbine discharge or total river flow, for test fish released at The Dalles Dam Spillway or Tailrace, 1997.

^a Average of hourly data weighted by fish number for counts of fish detected at the designated powerhouse multiplied by percentage of designated powerhouse flow of the total powerhouse flow or of total river flow.

^b Spillway Fish x PH % of PH flow minus Tailrace Fish x PH % of PH flow. Probability of mean difference = 0: 0.75 and 0.93 for spring and 0.10 and 0.21 for summer at first and second powerhouse, respectively.

^c Spillway Fish x PH % of Total flow minus Tailrace Fish x PH % of Total flow. Probability of mean difference = 0: 0.67 and 0.46 for spring and 0.18 and 0.34 for summer at first and second powerhouse, respectively.

^d Index for spill percent (64 or 30) and day or night (D or N) for condition and period of fish releases at The Dalles Dam.

^e Indicates fish releases that were not mixed according to the Monte Carlo approximation of the exact method.

Appendix Table B14. Comparisons of average of hourly fish counts multiplied by percent flow at Bonneville Dam First or Second Powerhouse, in relation to total turbine discharge or total river flow, for test fish released at The Dalles Dam Spillway or Tailrace, 1998.

^a Average of hourly data weighted by fish number for counts of fish detected at the designated powerhouse multiplied by percentage of designated powerhouse flow of the total powerhouse flow or of total river flow.

^b Spillway Fish x PH % of PH flow minus Tailrace Fish x PH % of PH flow. Probability of mean difference = 0: 0.33 and 0.22 for spring and 0.76 and 0.49 for summer at first and second powerhouse, respectively.

^c Spillway Fish x PH % of Total flow minus Tailrace Fish x PH % of Total flow. Probability of mean difference = 0: 0.80 and 0.22 for spring and 0.99 and 0.24 for summer at first and second powerhouse, respectively.

^d Index for spill percent (64 or 30) and day or night (D or N) for condition and period of fish releases at The Dalles Dam.

^e Indicates fish releases that were not mixed according to the Monte Carlo approximation of the exact method.

Appendix Table B15. Means, Confidence Intervals (CI), *t*-tests, and Analysis of Variance for PIT-tag interrogations of The Dalles Dam passage survival study for summer migrating juvenile salmon at Bonneville Dam, bird colonies, and combined data 1999.

^a No significant difference in travel time was detected for north vs. middle vs. south released spillway groups ($P = 0.60-0.77$). Mean travel time of spillway groups was significantly different from tailrace released groups ($P = 0.0001$; spillway groups averaged 0.12 day longer). Mean travel time for fish groups detected at Bonneville First Powerhouse was significantly different from those detected at Bonneville Second Powerhouse ($P = 0.001$; PH 1 averaged 0.12 day longer). Mean travel time for nighttime releases was significantly different from daytime releases ($P = 0.05$; nighttime releases averaged 0.12 day longer).

^b Average travel time to Bonneville Dam increased through time, but was not strongly correlated with Julian date, $r = 0.55$.

^c River flow in thousand ft³/second by COE convention; 1,000 ft³/second = 28.3 m³/second. Average travel time to Bonneville Dam was not strongly correlated to flow, $r = -0.64$

Appendix Table B18. Comparisons of average of hourly fish counts multiplied by percent flow at Bonneville Dam First or Second Powerhouse, in relation to total turbine discharge or total river flow, for test fish released at The Dalles Dam Spillway or Tailrace, summer 1999.

^a Average of hourly data weighted by fish number for counts of fish detected at the designated powerhouse multiplied by percentage of designated powerhouse flow of the total powerhouse flow.

^b Average of hourly data weighted by fish number for counts of fish detected at the designated powerhouse multiplied by percentage of designated powerhouse flow of total river flow.

^c Spillway Fish x PH % of PH flow minus Tailrace Fish x PH % of PH flow.

^d Spillway Fish x PH % of Total flow minus Tailrace Fish x PH % of Total flow.

^e Index for spill percent (64 or 30) and day or night (D or N) for condition and period of fish releases at The Dalles Dam.

^f Indicates fish releases that were not mixed according to the Monte Carlo approximation of the exact method. A two-sample *t*-test was conducted on PH Difference and Total Difference for both Bonneville First and Second Powerhouses for fish releases that were not mixed compared to those that were mixed and there was no significant difference between them; P = 0.13-0.92.

Appendix Table B19. Correlation of relative spill passage survival of subyearling chinook salmon to conditions during passage^a; combined data 1997-1999.

Correlation coefficient: r = -0.49 0.08 0.44 0.44									
Linear regression R ² = 0.32: Ln Surv % = 0.7870 -0.0531(Temp) -0.00194(Spill %) + 0.00058(R.flow)									

^a Correlations were not calculated for Julian date, Spill %, Diel index, and Spillbay location because of interaction, the best evaluation was to use ANOVA.

^b Diel index, where 1 represents daytime releases and 2 represents nighttime releases.

Spillbay location where 1 = North, 2 = Middle and 3 = South.
